Comparative Study of Juvenile American Shad Populations by Fin Ray and Scute Counts

By

PAUL R. NICHOLS, Fishery Biologist (Research)

Bureau of Commercial Fisheries Biological Laboratory
Beaufort, N.C.

ABSTRACT

Forty-five juvenile American shad, Alosa sapidissima (Wilson), collections, from 10 major shad producing rivers along the Atlantic coast of North America, were examined to see if differences in meristic counts suggested evidence of discrete river populations. Four meristic characters--pectoral, dorsal, and anal fin rays and scutes--were used. The difference in the counts between locations and between years within rivers was small compared to that between rivers. The differences in counts between rivers indicated that discrete populations of juvenile shad occurred in rivers.

INTRODUCTION

In studies to discover causes of the decline in yield of American shad, Alosa sapidissima (Wilson), and to determine factors favoring recovery of the fishery, it was essential that the number and distribution of populations be known.

The shad is widely distributed along the Atlantic coast from the St. Lawrence River, Canada, to the St. Johns River, Fla. This species is anadromous, spending most of its life in the ocean, but ascending coastal rivers to spawn. The spawning migrations into the rivers begin earliest in the southern part of the range (November in St. Johns River, Fla.) and are progressively later northward (June in St. John River, Canada). A female spawns about 250,000 eggs, and hatching occurs in 6 to 8 days at a water temperature of 17° C. The young shad stay in the rivers until autumn, attaining a length ranging from 75 to 145mm., and then migrate to sea. After spending from 2 to 6 years in the ocean, shad return to the rivers to spawn. Those spawning in rivers south of Cape Hatteras, N.C., normally die after spawning, while north of Cape Hatteras the proportion of fish spawning for the second time or more progressively increases from about 15 to 25 percent in Chesapeake Bay tributaries to about 45 to 55 percent in the Connecticut River.

Several workers have reported evidence of different shad populations along the Atlantic coast. Differences between shad from different areas based on meristic counts (Fischler, 1959; Hildebrand and Schroeder, 1928; Hill, 1959; Vladykov and Wallace, 1938), growth rates (Hammer, 1942;[1] Hildebrand and Schroeder, 1928), and fecundity (Davis, 1957; Lehman, 1953) indicated the occurrence of different populations. Recapture on the spawning ground of shad tagged in prior seasons indicated that they returned to their native streams to spawn (Hollis, 1948; Nichols, 1960). Also, the fact that the runs in the northern rivers were self-perpetuating and fluctuated independently (Talbot and Sykes, 1958) suggested different populations.

The purpose of this study was to determine if discrete populations of shad could be identified on the basis of consistent differences in counts of meristic characters in juveniles from 10 rivers. As used in this report, a "population" is a group of fish having similar meristic characteristics, of which the nature of origin, genotypic and/or phenotypic, of the characteristics has not been determined.

MATERIALS AND METHODS

For this study, the Atlantic coast was divided into three geographical areas: North Atlantic (Maine to Virginia); Chesapeake Bay (Maryland and Virginia); and South Atlantic (North Carolina to Florida). In 10 major shad producing rivers within these areas, 45 collections of juvenile shad, from 43 to 146 mm. fork length, were taken near spawning and

[1]The homing instinct of the Chesapeake Bay shad, Alosa sapidissima (Wilson), as revealed by a study of their scales. Thesis (typewritten), 1942, University of Maryland, 45 p.

nursery areas (table 1). Fifty specimens were sampled at random from each collection, covering the size range in each, for the analysis.

In the North Atlantic area, collections of juvenile shad were taken from the Connecticut and Hudson Rivers. From the Connecticut, collections were taken above South Hadley Falls Dam at Holyoke, Mass., about 85 miles from the river mouth, and at Enfield, Conn., about 15 miles downstream of South Hadley Falls Dam, in the fall of 1954, 1957, and 1958. The collections taken above South Hadley Falls Dam were considered as an introduced population, because the dam blocked upstream migrating fish from this area for more than 100 years until a fish-passage facility was installed in 1952. In the Hudson, collections were taken at Piermont, N.Y., in the brackish water section about 30 miles from the river mouth; at Kingston Point, N.Y., in the freshwater section about 50 miles upstream from Piermont; and at Catskill, N.Y., about 25 miles upstream from Kingston Point, in the autumn of 1950 and 1951. Additional collections were taken at Kingston Point in 1954, 1957, and 1958.

In the Chesapeake Bay area, collections of juvenile shad were taken from the Susquehanna, Rappahannock, York, and James Rivers. From the Susquehanna River, collections were taken below the Conowingo Dam in 1958; from the Rappahannock River, at Long Point in 1954 and in Batchelors Bay in 1958; from the York River, at the Pamunkey Indian Reservation in 1953, 1954, 1956, and 1958 and at the Mattaponi Indian Reservation in 1954 and 1958; and from the James River, at Walcot Wharf, Va., in 1954 and at Claremont Beach, Va., in 1954 and 1958.

In the South Atlantic area, collections of juvenile shad were taken from the Neuse, Edisto, Ogeechee, and St. Johns Rivers. From the Neuse River, collections were taken at Bridgeton, N.C., in 1950, 1954, 1957, and 1958 and at Streets Ferry, N.C., in 1954; collections from the Edisto River at Crosby Landing, S.C., were available for 1938 and 1939 and were taken in 1957 and 1958; collections from the Ogeechee River were available for 1938 and 1939 from Kings Ferry, Ga., and were taken in 1957 and 1958 at the State Park, near Richmond Hill, Ga.; and collections from the St. Johns River were taken at Mandarin, Fla., in 1954, in Lake Harney in 1954, and at Palatka, Fla., in 1954, 1957, and 1958.

Using a binocular microscope, counts were made of left pectoral, dorsal, and anal fin rays and total scutes. Fin ray counts included all rudiments, and the last elements in anal and dorsal fins, originating from the same base, were counted as one ray. The dorsal fin origin often required dissection to expose embedded rays. Scales occasionally had to be removed to expose enveloped scutes and anal fin rays. No attempt was made to separate scutes into anterior and posterior counts. Not a single abnormal fin or scute was encountered out of the 2,250 specimens examined.

Analysis of variance (Snedecor, 1956; Steel and Torrie, 1960) was used to test if meristic count means of specimens were statistically different at the 1 percent level (indicated by two asterisks in the tables) between rivers, locations within rivers, and years within rivers. Before comparing the means, group variances were tested for homogeneity.

ANALYSES OF MERISTIC COUNTS

Differences and similarities in meristic counts for samples of shad from within individual rivers and between rivers are discussed in the following sections by geographical area.

North Atlantic Area

Meristic counts were made of juvenile shad taken at each location in the Connecticut and Hudson Rivers (tables 2 and 3).

Connecticut River.--Mean meristic counts for the Holyoke samples (above Hadley Falls Dam) in most instances were slightly higher than those for Enfield samples (below Hadley Falls Dam). The difference in pectoral fin ray counts was significant between locations (table 4). The difference in each mean meristic count was nonsignificant between years for the Enfield samples. No analysis was made for differences between years in the meristic counts from above Hadley Falls Dam.

Hudson River.--Differences in meristic counts were not significant between locations (Piermont-Kingston-Catskill) for the years 1950 and 1951. Since Kingston Point was the

only location that had a sufficient number of data for comparing different young, samples taken at Kingston Point only were used to test for differences between years. There were no significant differences between years (1950, 1951, 1954, 1957, 1958) for these samples (table 4).

Comparison between Connecticut and Hudson Rivers.--Differences in the meristic counts for the Hudson and Connecticut Rivers samples were tested for significance only for the years for which collections were available from both rivers (1954, 1957, 1958). Therefore, only the collections taken at Kingston Point on the Hudson and at Enfield on the Connecticut were used in the comparisons. The Enfield samples were considered representative of the Connecticut River population, while the Kingston Point sample was considered representative of the Hudson River population.

The mean meristic counts for Hudson River shad generally were higher than those of Connecticut River fish. Significant differences were found between rivers for all meristic counts, except anal fin rays (table 4). The interaction between years and rivers was not significant. The significant difference in three of the four counts indicated that discrete populations occurred in each river.

Table 4.--Analysis of variance on meristic counts for differences between locations and between years within rivers, and differences between rivers, for samples of juvenile American shad from the Connecticut and Hudson Rivers

River	Component	Degrees of freedom (n_1,n_2)	F-value

Chesapeake Bay Area

Frequencies of the meristic counts for the samples of juvenile shad from the Chesapeake Bay tributaries are given in tables 5, 6, 7, and 8.

Susquehanna River.--Only one sample of juvenile shad was available from the Susquehanna River, collected in 1958 below Conowingo Dam (table 5), so no comparisons could be made.

Rappahannock River.--Mean meristic counts for the Rappahannock River samples were similar, and tests for differences in the counts between years were not significant (table 6). No comparisons were made, because the only sample taken in each of the two years was taken at different locations.

York River.--Mean meristic counts for the York River samples were similar between years and locations (table 7). Based on the

Claremont Beach samples the differences between years were not significant.

Comparison between Chesapeake Bay tributaries.--Data for all locations and all years for which collections were available were combined in testing for significant differences in meristic counts between two rivers. There was a significant difference in the meristic counts between the York and James fish in all instances; between the Rappahannock and James, the Rappahannock and York, and the James and Susquehanna in three instances; and between the Rappahannock and Susquehanna, and the York and Susquehanna in two instances (table 9). Where applicable, the interaction between years and rivers was not significant. The differences in meristic counts between rivers indicated that discrete populations of shad occurred in the Chesapeake Bay tributaries.

South Atlantic Area

Meristic counts were made of juvenile shad taken for certain years at locations in the Neuse, Edisto, Ogeechee, and St. Johns Rivers of the South Atlantic area (tables 10, 11, 12, and 13).

Neuse River.--Based on the 1954 samples (table 10), differences in the meristic counts were not significant between the Bridgeton and Streets Ferry samples. Differences in the meristic counts were not significant between years for the Bridgeton samples (table 14).

Edisto River.--Samples were collected from only one location in the Edisto River (table 11). The differences in the counts between years were not significant (table 14).

Ogeechee River.--Since samples were obtained in different years from the two locations in the Ogeechee River, each location was analyzed separately in testing for differences in meristic counts between years, and no comparisons were made between locations (table 12). The differences in the counts between years were not significant (table 14).

RELATION BETWEEN MERISTIC COUNTS AND OTHER FACTORS

In certain instances significant differences were found in meristic counts between young shad from neighboring streams and among streams within large geographical areas. Whether the cause of these differences was primarily genetic or was environmental variation under which the fish developed, or a combination of both, would not affect the findings. Physical and chemical data on the environment at spawning time were not available, so the relation between differences or shifts in meristic counts between two separate rivers and environmental factors was not known. Lindsey (1957), Raney and Woolcott (1955), and Tåning (1952), and others, although working on species other than shad, listed temperature as the obvious environmental factor that may produce differences at the time these characters are formed in the embryo. Although shad spawn earlier in southern rivers and progressively later in northern rivers, widely separated populations spawn and eggs and larvae develop under about the same water temperature range. Laboratory rearing of the species under controlled conditions would be needed to demonstrate clearly the relation between meristic counts and temperature.

There was no consistent latitudinal cline in the meristic counts examined over the entire geographic range sampled. Fin ray counts were higher in southern rivers and lower in northern rivers, with intermediate counts in between. Scute counts were higher in northern rivers and lower in southern rivers. The Connecticut River samples had the lowest mean count in pectoral and dorsal fin rays, and the St. Johns River samples had the highest mean counts in dorsal and anal fin rays. However, the mean scute counts, which showed the greatest difference, reversed this pattern with the high in the Hudson River being more than one unit larger than the low counts in the Neuse River.

There were slight variations in meristic counts on juvenile shad between years and locations within a river, but these were not significant and were small compared to the differences in the counts between rivers. The differences in meristic counts between rivers indicated that discrete juvenile populations exist. For a better understanding of shad populations, future work should include studies of the relation between the meristic counts of juvenile shad and environmental variations under which the fish developed.

SUMMARY

To test if shad populations in various rivers could be separated by differences in meristic count, collections of juvenile shad from 10 rivers along the Atlantic coast were compared by analysis of variance. Counts of pectoral, dorsal, and anal fin rays and scutes were used.

Differences in counts of meristic characteristics within individual rivers and between rivers within geographical areas were as follows:

1. Within individual rivers, no significant differences were found between locations and between years except between locations for pectoral fin rays in the Connecticut River.

2. In the North Atlantic area, significant differences were found between the Hudson and Connecticut Rivers for all counts except anal fin rays.

3. In Chesapeake Bay tributaries, significant differences were found between the York and James Rivers for all counts; between the Rappahannock and James Rivers, the Rappahannock and York Rivers, and the James and Susquehanna Rivers for three of the counts; and between the Rappahannock and Susquehanna, and the York and Susquehanna Rivers for two of the counts.

4. In the South Atlantic area, significant differences were found between the Neuse and Edisto Rivers, and the Neuse and St. Johns

Rivers for three of the counts; between the Neuse and Ogeechee Rivers, and the Ogeechee and Edisto Rivers for two of the counts; and between the Ogeechee and St. Johns Rivers for one of the counts.

These findings indicated that discrete populations of shad occurred in Atlantic coast rivers.

ACKNOWLEDGMENTS

William H. Massmann[2] provided collections of juvenile shad from the York River taken in 1954 and 1956, and Richard R. Whitney[3] gave collections from the Susquehanna River taken in 1958. Edward C. Raney of Cornell University, Ithaca, N.Y., loaned collections from the Rappahannock and James Rivers taken in 1954.

Created in 1849, the Department of the Interior--a department of conservation--is concerned with the management, conservation, and development of the Nation's water, fish, wildlife, mineral, forest, and park and recreational resources. It also has major responsibilities for Indian and Territorial affairs.

As the Nation's principal conservation agency, the Department works to assure that nonrenewable resources are developed and used wisely, that park and recreational resources are conserved for the future, and that renewable resources make their full contribution to the progress, prosperity, and security of the United States--now and in the future.
